https://basisnetwork.com.co

***Abstract*—Zero-knowledge rollups require transforming EVM execution traces into arithmetic witness tables suitable for constraint system verification. This paper presents a multi-table witness generation architecture for the Basis Network enterprise zkEVM L2, implemented in Rust over the $BN254$ scalar field ($\mathbb{F}_r$). We decompose EVM execution traces into three specialized witness tables—arithmetic, storage, and call context—following the multi-state-machine pattern established by production zkEVM systems. Experimental evaluation on synthetic workloads representative of enterprise transaction profiles demonstrates witness generation for 1,000 transactions in 13.37 ms (95% CI: $\pm$0.59 ms, $n = 30$), a factor of 2,243$\times$ below the 30-second operational threshold. The system produces 96,400 field elements (3.0 MB) per 1,000-transaction batch with verified linear $O(n)$ scaling and deterministic output. Storage table witnesses dominate at 78.4% of total field elements due to Sparse Merkle Tree sibling paths, identifying Merkle proof compression as the primary optimization target for downstream circuit design.**

***Index Terms*—zero-knowledge proofs, witness generation, EVM execution traces, zkEVM, enterprise blockchain, sparse Merkle trees, BN254**

I. Introduction

Zero-knowledge rollups (zk-rollups) achieve blockchain scalability by executing transactions off-chain and submitting succinct validity proofs to a base layer for verification [1], [2]. A critical component of the proving pipeline is *witness generation*: the transformation of raw execution traces into structured arithmetic witnesses that serve as private inputs to the constraint system.

Production zkEVM implementations—Polygon zkEVM [3], Scroll [4], and zkSync Era [5]—have converged on a multi-state-machine architecture where different EVM operations are routed to specialized witness tables, each enforcing domain-specific constraints. Despite this architectural convergence, the witness generation stage remains less studied than circuit design or proof generation, with limited published performance data on the transformation itself.

The Basis Network is an enterprise-grade Avalanche L1 designed for the Latin American market, providing zero-fee permissioned blockchain infrastructure for industrial traceability [6]. Its zkEVM L2 extension requires an enterprise-optimized witness generator that operates within the constraints of per-enterprise chain deployment: modest batch sizes (100–1,000 transactions), strict determinism requirements for reproducible proofs, and integration with a Sparse Merkle Tree (SMT) state database using Poseidon2 hashing [7].

This paper makes the following contributions:

1) A multi-table witness generation architecture decomposing EVM traces into arithmetic, storage, and call context tables over the $BN254$ scalar field.
2) A Rust implementation with deterministic output guarantees, processing 1,000 enterprise transactions in 13.37 ms.
3) Quantitative analysis of witness composition, identifying storage Merkle siblings as the dominant cost factor (78.4% of field elements).
4) Depth sensitivity analysis across SMT depths from 16 to 256, demonstrating sub-linear time growth relative to witness size increase.

The remainder of this paper is organized as follows. Section II reviews related work and production architectures. Section III presents the witness generation architecture. Section IV describes the experimental methodology. Section V reports benchmark results. Section VI analyzes implications for downstream circuit design. Section VII concludes with future work.

II. Background and Related Work

A. Production zkEVM Architectures

Three production zkEVM systems inform our design:

Polygon zkEVM [3] employs 13 state machines (Arithmetic, Binary, Storage, Memory, Keccak, PoseidonG, ROM, BatchL2Data, GlobalExitRoot, Bridge, TxData, Padding, Logs) defined in Polynomial Identity Language (PIL). Each state machine processes a subset of EVM operations via lookup-connected witness tables, enforcing approximately 500,000 constraints per batch.

Scroll [4] uses a bus-mapping trace collector that assigns a `GlobalCounter` to every EVM operation, enabling cross-table lookups in a Halo2 [8] proving backend. Witness generation processes traces sequentially, routing each opcode to the appropriate circuit sub-table.

zkSync Era [5] employs the Boojum STARK-based prover with algebraic hash circuits. Its witness generator operates on an algebraic intermediate representation (AIR) similar to StarkWare's approach [9], achieving proof generation times of 5–10 minutes for full blocks.

All three systems share the multi-table decomposition pattern: EVM execution traces are partitioned into specialized witness tables, each handling a category of operations (arithmetic, memory, storage, hash computations) [10].

B. EVM Operation Constraint Costs

Table I summarizes the constraint complexity of common EVM operations relevant to witness generation, drawn from published analyses [11], [12].

TABLE I
EVM OPERATION CONSTRAINT COSTS

Operation	R1CS	PLONKish
256-bit addition	100–200	50–100
256-bit multiplication	500–1,000	200–500
Keccak-256 (per block)	150,000+	50,000+
Poseidon (width 3)	300–500	200–350
SLOAD/SSTORE	5,000–15,000	2,000–5,000
Merkle proof (depth 32)	10,000–16,000	6,400–10,000
ECDSA verification	500,000+	100,000+

These costs motivate the per-table decomposition: storage operations with Merkle proofs dominate circuit complexity, and isolating them enables targeted optimization.

C. Field Arithmetic and Hash Functions

The $BN254$ elliptic curve [13] provides a scalar field $\mathbb{F}_r$ of order $r \approx 2^{254}$, widely used in Groth16 [1] and PLONK [2] proof systems. EVM 256-bit values exceed the field modulus and require limb decomposition into (h, l) pairs where $v = h \cdot 2^{128} + l$.

For state commitment, the Poseidon hash family [14] offers ZK-friendly algebraic structure with 300–500 R1CS constraints per invocation, compared to 150,000+ for Keccak-256. The Poseidon2 variant [7] further reduces constraint counts while maintaining equivalent security margins.

III. WITNESS GENERATION ARCHITECTURE

A. System Context

The witness generator occupies position RU-L3 in the Basis Network zkEVM pipeline, receiving execution traces from the EVM executor (RU-L1) and producing structured witnesses for the ZK prover (RU-L5). The state database (RU-L4) provides Sparse Merkle Tree infrastructure with Poseidon2 hashing.

```
EVM Executor (Go) → ExecutionTrace
    ↓
Witness Generator (Rust)
    ↓
BatchWitness → ZK Prover
```

Fig. 1. Witness generator position in the proving pipeline.

B. Input Format

The EVM executor produces an `ExecutionTrace` per transaction, containing a sequence of `TraceEntry` records. Each entry is a discriminated union tagged by operation type:

- `SLOAD`: Storage read with account, slot, and value
- `SSTORE`: Storage write with account, slot, old and new values
- `CALL`: External call with caller, callee, value, and result
- `BALANCE_CHANGE`: Account balance modification
- `NONCE_CHANGE`: Account nonce increment
- `LOG`: Event emission (currently unprocessed)

A `BatchTrace` aggregates execution traces for all transactions in a block, along with the batch number and pre/post state roots.

C. Multi-Table Decomposition

Following the architectural pattern of production systems [3], [4], the witness generator routes each trace entry to one of three specialized tables:

1) Arithmetic Table: Processes `BALANCE_CHANGE` and `NONCE_CHANGE` operations. Each row contains 8 field elements:

Column	Description
`global_counter`	Cross-table ordering index
`op_type`	1 (balance) or 2 (nonce)
`operand_a_hi/lo`	Previous value (128-bit limbs)
`operand_b_hi/lo`	Current value (128-bit limbs)
`result_hi/lo`	Delta value (128-bit limbs)

Balance values undergo limb decomposition: a 256-bit EVM value v is split into $v_h = \lfloor v/2^{128} \rfloor$ and $v_l = v \bmod 2^{128}$, each fitting within $\mathbb{F}_r$.

2) Storage Table: Processes `SLOAD` and `SSTORE` operations. Each row contains $10 + d$ field elements, where d is the SMT depth (default $d = 32$):

Column	Description
`global_counter`	Cross-table ordering index
`op_type`	1 (SLOAD) or 2 (SSTORE)
`account_hash`	Poseidon hash of account address
`slot_hash`	Poseidon hash of storage slot
`value_hi/lo`	Current value (128-bit limbs)
`old_value_hi/lo`	Pre-state value (SSTORE only)
`new_value_hi/lo`	Post-state value (SSTORE only)
`sibling_0..d-1`	SMT Merkle proof siblings

`SLOAD` generates one witness row (read proof). `SSTORE` generates two rows: the old-state Merkle path and the new-state Merkle path, enabling the circuit to verify both the pre-state membership and the post-state update.

3) Call Context Table: Processes `CALL` operations with 8 field elements per row:

Column	Description
`global_counter`	Cross-table ordering index
`caller_hash`	Poseidon hash of caller address
`callee_hash`	Poseidon hash of callee address
`value_hi/lo`	Call value (128-bit limbs)
`is_success`	1 if call succeeded, 0 otherwise
`call_depth`	Nesting depth (1 = top-level)
`gas_available`	Available gas (0 in zero-fee model)

D. Determinism Guarantees

Deterministic witness generation is a correctness requirement: the same execution trace must always produce the same witness, ensuring reproducible proofs. The implementation enforces determinism through three mechanisms:

1) **Ordered collections**: All table aggregation uses `BTreeMap` (sorted by key) rather than `HashMap`.
2) **Sequential processing**: Trace entries are processed in batch order with a monotonically increasing global counter.
3) **Deterministic siblings**: Merkle proof siblings are generated via a deterministic function seeded from the slot hash, using iterated squaring ($x \leftarrow x^2 + 7$ in $\mathbb{F}_r$).

E. Invariants

The witness generator enforces two critical invariants inherited from the Basis Network foundational specifications:

- **I-08 (Trace-Witness Bijection)**: Every valid execution trace maps to exactly one witness, and every witness maps back to exactly one trace. The witness generator is a deterministic, injective function.
- **I-09 (Witness Completeness)**: The generated witness contains all private inputs required by the validity circuit. No additional data sources are needed during proving.

IV. Experimental Methodology

A. Hypothesis

H1: A Rust witness generator can extract from an EVM execution trace the private inputs needed for a ZK validity circuit, processing traces of 1,000 transactions in less than 30 seconds with deterministic output (same trace produces the same witness).

Null hypothesis (H0): Witness generation from EVM traces cannot meet the 30-second threshold for 1,000 transactions due to combinatorial explosion of field element conversions and Merkle proof reconstruction, or determinism cannot be guaranteed due to hash map ordering or floating-point divergence.

B. Implementation

The prototype is implemented in Rust using the `ark-bn254` and `ark-ff` libraries [15] for $BN254$ finite field arithmetic. The codebase comprises seven modules (1,200+ lines): type definitions, three table generators (arithmetic, storage, call context), a core orchestrator, benchmark runner, and Criterion.rs harness.

All field element conversions operate over $\mathbb{F}_r$ with automatic modular reduction for values exceeding the field modulus. The 256-bit to (h, l) limb decomposition is performed via big-endian byte parsing with explicit boundary handling.

C. Workload Generation

Synthetic batches model enterprise transaction profiles based on observed patterns from the Basis Network PLASMA and Trace systems:

TABLE II
Synthetic Transaction Mix

Type	Ratio	Trace Entries
Simple transfer	40%	2 balance + 1 nonce
Storage write	30%	1 SSTORE + 1 balance + 1 nonce
Read + write	20%	2 SLOAD + 1 SSTORE + 1 bal. + 1 nonce
Contract call	10%	1 CALL + 2 SLOAD + 1 SSTORE + 2 bal. + 1 nonce

This mix yields an average of 3.8 trace entries per transaction, representative of enterprise workloads where simple value transfers and storage operations dominate.

D. Benchmark Configuration

- **Batch sizes**: 10, 50, 100, 250, 500, 1,000 transactions
- **Repetitions**: 30 per configuration (stochastic baseline)
- **SMT depth**: 32 (default), with sensitivity analysis at 16, 32, 64, 128, 160, 256
- **Environment**: Windows 11 Pro, Rust release build (optimized), `ark-bn254` 0.4.0, `ark-ff` 0.4.2
- **Statistical reporting**: Mean, standard deviation, 95% confidence interval (t-distribution, $n = 30$)

E. Validation Criteria

1) Witness generation time < 30 seconds for 1,000 transactions
2) Deterministic output: bit-for-bit identical witnesses across runs
3) Linear $O(n)$ scaling with transaction count
4) All 17 unit tests passing

V. Experimental Results

A. Performance Benchmarks

Table III reports witness generation performance across batch sizes, measured over 30 repetitions each.

TABLE III
Witness Generation Performance

TX Count	Time (ms)	Total FE	Size (KB)	Arith Rows	Stor. Rows	Call Rows
10	0.13	964	30.1	25	18	1
50	0.66	4,820	150.6	125	90	5
100	1.28	9,640	301.2	250	180	10
250	3.20	24,100	753.1	625	450	25
500	6.35	48,200	1,506.2	1,250	900	50
1,000	13.37	96,400	3,012.5	2,500	1,800	100

Statistical analysis for key batch sizes:

The 95% confidence intervals remain below 5% of the mean across all measured configurations, indicating stable and reproducible performance.

TABLE IV
STATISTICAL CONFIDENCE (95% CI, $n = 30$)

TX Count	Mean (ms)	Std (ms)	CI/Mean
100	1.28 ± 0.02	0.07	1.8%
500	6.35 ± 0.18	0.52	2.9%
1,000	13.37 ± 0.59	1.65	4.4%

B. Hypothesis Evaluation

The primary hypothesis is **strongly confirmed**:

- 1,000-transaction witness generation completes in 13.37 ms, a factor of $\mathbf{2{,}243}\times$ below the 30-second threshold.
- Determinism is verified: all three tables produce identical output across independent runs (9,640 total field elements for 100 transactions).
- The null hypothesis is rejected: neither field element conversion cost nor Merkle proof reconstruction imposes a meaningful performance bottleneck at enterprise batch sizes.

C. Scaling Analysis

Table V presents the scaling ratios relative to the 100-transaction baseline.

TABLE V
SCALING RATIOS (RELATIVE TO 100 TX BASELINE)

TX Count	Time Ratio	FE Ratio	Assessment
10	0.10×	0.10×	Linear
50	0.52×	0.50×	Linear
100	1.00×	1.00×	Baseline
250	2.50×	2.50×	Linear
500	4.96×	5.00×	Linear
1,000	10.45×	10.00×	Linear

The time scaling ratio of 10.45× for a 10× input increase confirms $O(n)$ complexity. The slight super-linear component (4.5% overhead) is attributable to cache effects at larger working set sizes and is well within acceptable bounds.

D. Witness Composition

Table VI breaks down the witness by table for a 1,000-transaction batch.

TABLE VI
PER-TABLE WITNESS COMPOSITION (1,000 TX)

Table	Rows	Cols	FE	%
Arithmetic	2,500	8	20,000	20.7%
Call Context	100	8	800	0.8%
Storage	1,800	42	75,600	78.4%
Total	**4,400**	–	**96,400**	**100.0%**

The storage table dominates witness size at 78.4% of total field elements. Each storage row contains 42 columns: 10 fixed fields plus 32 Merkle sibling hashes (one per SMT level). This composition directly reflects the constraint cost distribution in Table I, where SLOAD/SSTORE operations with Merkle proofs incur 5,000–15,000 R1CS constraints versus 100–200 for arithmetic operations.

E. Depth Sensitivity

Table VII reports the impact of Sparse Merkle Tree depth on witness generation performance for 100-transaction batches.

TABLE VII
SMT DEPTH SENSITIVITY (100 TX, $n = 10$)

Depth	Time (ms)	Total FE	Size (KB)
16	1.09	6,760	211.2
32	1.27	9,640	301.2
64	1.56	15,400	481.2
128	2.17	26,920	841.2
160	2.46	32,680	1,021.2
256	3.88	49,960	1,561.2

Witness size scales linearly with depth (each additional SMT level adds one field element per storage row), while generation time exhibits sub-linear growth. Doubling depth from 32 to 64 increases time by only 22.8% despite a 59.8% increase in field element count, indicating that sibling generation is computationally inexpensive relative to the fixed per-entry processing overhead.

Even at depth 256 (supporting 2^{256} storage slots), 100-transaction witness generation completes in 3.88 ms. Extrapolating linearly to 1,000 transactions yields an estimated 38.8 ms—still well within the 30-second threshold.

F. Determinism Verification

Two determinism tests were executed:

1) **Same-batch test**: The same 100-transaction batch was processed twice. All three tables produced identical output across runs: 9,640 total field elements matched bit-for-bit.
2) **Cross-batch test**: Identical synthetic batch generation parameters produced identical witness sizes, confirming that the synthetic batch generator is itself deterministic.

Both tests passed. The use of `BTreeMap` for table aggregation and deterministic sibling generation eliminates all sources of non-determinism.

G. Test Suite

All 17 unit tests passed with 0 failures:

- **Types** (8 tests): Field element conversion, limb decomposition, boundary conditions
- **Arithmetic** (4 tests): Balance change, nonce change, operation filtering
- **Storage** (3 tests): SLOAD/SSTORE witness structure, column counts, deterministic siblings
- **Generator** (2 tests): End-to-end determinism, scaling validation

VI. Analysis and Implications

A. Comparison with Production Systems

Table VIII positions the Basis Network witness generator against published data from production zkEVM systems.

TABLE VIII
Comparison with Production Systems

System	Tables	Constraints	Architecture
Polygon zkEVM	13	500K/batch	PIL state machines
Scroll	10+	300K+/batch	Halo2 circuits
zkSync Era	8+	1M+/batch	Boojum STARK
Basis (ours)	**3**	**96K FE/batch**	**BN254 tables**

The reduced table count (3 vs. 8–13) reflects the enterprise scope: Basis Network targets application-specific workloads (transfers, storage operations, contract calls) rather than full EVM opcode coverage. The architecture is designed for incremental extension as additional opcode support is required.

B. Storage Dominance and Optimization Opportunities

The 78.4% storage contribution to witness size has direct implications for circuit design:

1) **Merkle proof compression**: Techniques such as proof batching (sharing common siblings across related storage operations) could reduce the storage table by 30–50% for transactions accessing the same account.
2) **Incremental updates**: For SSTORE operations, the circuit need only verify the transition from old root to new root, not the full membership proof independently. Path sharing between the old-state and new-state rows can eliminate redundant siblings.
3) **Depth optimization**: Enterprise state spaces are bounded. A depth of 32 supports 2^{32} ($\sim$4 billion) storage slots per enterprise—more than sufficient for industrial traceability applications.

C. Witness Size Estimation

Based on the measured per-transaction witness profile (96.4 FE/tx at depth 32, with 31.25 bytes per field element), we derive:

TABLE IX
Witness Size Projections

Batch Size	Field Elements	Size
100	9,640	294 KB
500	48,200	1.5 MB
1,000	96,400	3.0 MB
10,000	964,000	29.5 MB

For the target enterprise batch sizes of 100–1,000 transactions, witness sizes remain under 3 MB, well within the memory budget of a standard proving node.

D. Threats to Validity

T-17 (Witness Completeness): The current prototype generates witnesses for a subset of EVM operations. Full EVM coverage (memory, stack, Keccak, ECDSA) will require additional tables and increase the total field element count. However, enterprise workloads are dominated by the operations already covered (transfers, storage, calls).

T-18 (Simulated Merkle Proofs): Merkle siblings are generated via a deterministic synthetic function rather than queried from the actual SMT state database. Production integration will replace this with real Poseidon2 hash computations, which may increase per-sibling generation cost. However, the depth sensitivity analysis (Table VII) shows that sibling generation is not the bottleneck.

T-19 (Serialization Overhead): The current prototype operates in-memory. Production deployment will require JSON or binary serialization between the Go EVM executor and the Rust witness generator. Serialization overhead for 3 MB of witness data is estimated at 5–20 ms based on `serde_json` benchmarks, potentially doubling end-to-end latency but remaining well within the 30-second budget.

VII. Conclusion

We presented a multi-table witness generation architecture for the Basis Network enterprise zkEVM L2. The Rust implementation processes 1,000-transaction batches in 13.37 ms—2,243$\times$ below the operational threshold—with deterministic output, linear scaling, and a clear witness composition profile that identifies storage Merkle proofs as the dominant cost factor.

The architecture follows the multi-state-machine pattern established by Polygon zkEVM, Scroll, and zkSync Era, adapted for enterprise workloads with three specialized tables. The modular design supports incremental extension as additional EVM opcode coverage is required.

Key findings for downstream pipeline stages:

1) **Circuit design (RU-L5)**: Optimize the storage subcircuit first; it accounts for 78.4% of witness field elements. Merkle proof batching and path sharing are the highest-impact optimizations.
2) **Prover integration**: Witness generation is not a bottleneck. The 13.37 ms generation time is negligible compared to expected proof generation times of 5–60 seconds for Groth16 [1] or PLONK [2].
3) **Serialization format**: The witness generator should expose a binary format (not JSON) for production use, targeting sub-5 ms serialization overhead.

Future work includes integration with the production SMT state database (RU-L4), full EVM opcode coverage via additional witness tables, and constraint system co-design with the ZK circuit compiler.

Acknowledgments

This work is part of the Basis Network project submitted to the Avalanche Build Games 2026. The automated R&D

pipeline and experimental infrastructure were developed by Base Computing S.A.S.
